PERFORMANCE

ELEVATED

CDN MISCONFIGURATION

A configuration change accidentally bypassed the CDN entirely. Every image, stylesheet, and static asset is now hitting your origin servers directly. Load has spiked 40× and global page load times have tripled.

CDN misconfigurations are a classic example of infrastructure change risk. A CDN can absorb 80–95% of total traffic for content-heavy applications — losing it instantaneously overwhelms origin infrastructure. The DevOps safeguard is Infrastructure as Code: CDN configuration defined in Terraform, Pulumi, or CloudFormation, stored in version control, reviewed via pull request, and deployed through the same CI/CD pipeline as application code. This makes every change auditable and reversible. Cache-Control headers should be explicitly set — implicit or inherited caching behaviour is fragile. Canary deployments apply to infrastructure changes too: roll out config changes to a percentage of edge nodes before applying globally.

Infrastructure config is code. It should be reviewed, tested, and reversible as easily as application code.

TEAM DISCUSSION

Do you have infrastructure-as-code with change review? Can you safely revert a config change in under five minutes?
